

What the physics head sees

the three closed-form input maps for one held-out super-emitter scenario (6 masts, 126 kg h⁻¹), computed from measured wind only; maps B-D are the network's extra input

A. What the sensors observed

dot size = peak methane reading;
arrow = measured wind

B. Source evidence

dark = a leak here explains
the observed readings

C. Wind sensitivity

dark = evidence unstable
under anemometer error

D. Sensor visibility

dark = a leak here would be
seen by many masts

E. Exact Bayes reference (known wind)

with the true wind, the posterior concentrates
onto essentially one grid cell — wind error is the whole game

- sensor masts (6)
- ★ true methane source

The three maps (B-D) are the network's
entire extra input — closed-form physics,
computed from measured wind only,
averaged over the same $K = 8$ wind draws.

The residual (fit-quality) map of the
earlier method was dropped: the final
method is these three channels.
